Nanostructured thin silicon-based films have been deposited using the hot-wire chemical vapour deposition (HWCDV) technique at the University of the Western Cape. A variety of techniques including optical and infrared spectroscopy, X-rays diffraction (XRD) and transmission electron microscopy (TEM) have been used for characterisation of the films. The electrical measurements show that the films have good values of photo-response, and the photocurrent remains stable after several hours of light soaking. This contribution will discuss the characteristics of the hydrogenated nanocrystalline silicon thin films deposited using increased process chamber pressure at a fixed hydrogen dilution ratio in monosilane gas.

Key words: hot-wire deposition, intrinsic, absorption coefficient, degradation measurements, stability, photoreponse

Methods

Thin films ranging from ~500 nm to 1 000 nm were deposited onto 2 cm × 2 cm Corning glass and c-Si (100) substrates. More details on the deposition chamber and the deposition process have been given elsewhere.\textsuperscript{5,6} The thickness was calculated using the computing method of Swanepoel\textsuperscript{11} and measured by a Dektak profilometer. For this effect, a Veeco Dektak 6M profilometer was used to take measurements electromechanically by moving the sample beneath a diamond-tipped stylus that rides over the sample surface. The scan traces were always taken from a bare area of the substrate to the surface of the deposited layer and average step heights were calculated to estimate the thickness using the interfaced software.\textsuperscript{12} To ensure that the films were free of impurities during growth, a background pressure of less than 10\textsuperscript{-2} mbar was always achieved before deposition. The tantalum filament catalyst consisted of seven parallel wires maintained at 1 600°C. The temperatures of the substrate heater (\(T_{\text{sub}}\)) were preset at 375°C, 410°C and 450°C. The distance between the filament and the substrate was fixed at 3.6 cm. Table 1 gives the details of the deposition conditions of the films used in this paper. The hydrogen dilution ratio in the silane gas was calculated as

\[
R_{\text{H}_2} = \left( \frac{\phi_{\text{H}_2}}{\phi_{\text{H}_2} + \phi_{\text{SiH}_4}} \right)
\]

where \(\phi_{\text{H}_2}\) and \(\phi_{\text{SiH}_4}\) represent the flow rates of hydrogen and silane, respectively. The phase changes were observed by XRD and by Raman scattering spectroscopy. X-ray diffraction spectra were obtained by means of a D8 advance Bruker diffractometer, a theta-2 theta (\(\theta-2\theta\)) machine situated at iThemba LABS, Faure. The used X-ray radiation was Cu K\(\alpha\), with a wavelength of 0.15 nm. The intensity of the diffracted radiation was detected as a function of 2\(\theta\). In this study the value of 2\(\theta\) varied from 22° to 70.72° with an angular resolution of 0.04° and an accumulation time of 30 s per step, i.e. 10 h per sample. Raman measurements were performed using the 514.5 nm line of a Spectra Physics Ar\textsuperscript{+}-ion laser, a SPEX triple-grating monochromator and a CCD-detector situated in the Physics Department, Utrecht University (the Netherlands). The crystalline volume fractions \((f_c)\) were calculated from the deconvoluted peaks using the Raman data according to

\[
f_c = \left( \frac{l_{c} + l_{gb}}{l_{c} + l_{gb} + l_{a}} \right)
\]

where \(l_{c}\), \(l_{gb}\) and \(l_{a}\) are the integrated intensities of the crystalline

peak, intermediate peak of the amorphous to crystalline phase, and the amorphous phase respectively.\textsuperscript{13} The hydrogen content (C\textsubscript{H}) was calculated from Fourier transform infrared spectroscopy measurements, using the integrated absorption coefficient of the rocking mode vibration at \textasciitilde 640 cm\textsuperscript{-1}.\textsuperscript{14} For dark conductivity and photoconductivity measurements, two silver electrodes with a length of 20 mm separated by a distance of 0.5 mm were deposited on the samples. The photoconductivity was measured using a solar simulator with the AM1.5 spectrum at an intensity of 100 mW cm\textsuperscript{-2} and an applied voltage of 100 V. For activation energy (E\textsubscript{a}) measurements, dark currents were measured from films successively annealed and cooled down in a vacuum from 160°C to room temperature. Activation energy was obtained from the Arrhenius plot of the dark conductivity data versus the reciprocal temperature in the cooling region. The light degradation experiment was done using the same setup as the one used by Britton \textit{et al.}\textsuperscript{16} The samples were illuminated for 300 h and the photocurrent was measured at different time intervals at an applied voltage of 50 V.

\textbf{Results and discussion}

\textbf{Phase transition}

Figure 1 displays the Raman spectra of the films deposited at a fixed hydrogen dilution ratio of 87\% with the deposition pressure varying from 20 µbar to 60 µbar. The first three samples deposited within the range 20–40 µbar were fully amorphous, as shown by the broad peaks centred around 480 cm\textsuperscript{-1}. The fourth sample deposited at a pressure of 60 µbar was just above the edge of crystallinity. Its Raman spectrum is showing an asymmetry towards 520 cm\textsuperscript{-1} and its deconvolution into different Gaussians produced a small peak around 506 cm\textsuperscript{-1} in addition to the amorphous one centred around 480 cm\textsuperscript{-1}. This has been interpreted as the inclusion of a finite number of small crystallites in an amorphous network. A crystalline volume fraction equal to 6\% was calculated for this sample. The abundance of atomic hydrogen on, or near, the growing surface is essential for a change from an amorphous phase to a crystalline phase\textsuperscript{4,17} as the atomic hydrogen is known to passivate the surface and to etch away weak Si-Si bonds in the subsurface region.\textsuperscript{18} An increase of the deposition pressure had the beneficial effect of increasing the silane conversion rate and thus generating more silicon and atomic hydrogen precursors. It was even easier to induce crystallinity by increasing the pressure within the same range of 20–60 µbar at a fixed hydrogen dilution ratio of 92\% as shown in Fig. 2,\textsuperscript{19} increasing values of hydrogen dilution ratio produced more atomic hydrogen resulting from an increased splitting of molecular hydrogen on the hot filament. In Fig. 2(i), an increasing trend of the peak centred around 515 cm\textsuperscript{-1} with an increase in pressure, is observed on the spectra corresponding to Samples 7–9. The increasing Raman intensity of this peak at increasing process pressure is indicating an increase of the crystalline volume fraction. Sample 6 remains amorphous as its Raman spectrum shows only a broad peak centred around 480 cm\textsuperscript{-1}. The XRD results in Fig. 2(ii) agreed well with the Raman results for Samples 6, 8 and 9. The XRD spectrum of Sample 7 was not conclusive enough, suggesting that, for films near the edge of crystallinity, a complementary sensitive method must be used to confirm the phase of the material. The UV-VIS reflection measurements on the same samples in Fig. 3 agreed with the XRD and Raman findings for the three investigated films (Samples 6, 8 and 9); the crystal Si direct-transition UV reflectance signatures at 365 nm and 275 nm\textsuperscript{20} revealed the presence of any crystalline phase at the surface. No crystalline signature was observed in the case of Sample 6, meaning that it was fully amorphous. The transition peaks for Samples 8 and 9 are distinguishable around 275 nm; they are not sharp as in the case of the c-Si substrate due to the residual amorphous network. Figure 4 displays the typical cross-section transmission electron micrographs of a nc-Si:H film near the edge of crystallinity with a crystalline volume fraction of 8\% and a µc-Si:H film with f\textsubscript{c} of 53\%. They are identified as Samples 10 and 11 in Table 1. The dark regions dispersed in much brighter areas are the crystals embedded in an amorphous network. The crystal sizes observed from TEM fell in the calculated range of about 2–40 nm as determined by the Scherrer formula on XRD data.

\end{figure}
Deposition rate

Figure 5 shows the deposition rate against the deposition pressure at a fixed hydrogen dilution ratio of 87%; it is observed that the deposition rate increased with an increase in pressure until a point where it saturated. The supply of Si-containing radicals increased with the process pressure; but since the surface of the filament was limited, a saturation point of the decomposition of the feed gas would have been reached and thus the deposition rate saturated. For the films deposited at a higher hydrogen dilution of 92%, at increasing chamber pressures within the same range of 20–60 µbar, slower growth rates were observed (2.17–3.00 Å s⁻¹). This is explained by both the depletion of the SiH₄ gas in the chamber resulting in less species decomposed on the filament for film growth, and the increase of H₂ in the chamber giving rise to the concentration of atomic hydrogen decomposed from the filament that, in turn, increased the etching effect on the growing surface.

Absorption coefficient

Figure 6 shows the absorption coefficient (α) spectra for films ranging from amorphous to microcrystalline silicon. They were processed using the deposition conditions of Samples 6–9 as given in Table 1. As expected, the amorphous sample deposited with a deposition pressure of 20 µbar had higher α-values in the visible part of the spectrum than the microcrystalline films. Its value at 2 eV (~600 nm) was greater than the minimum reference value of 3.5 × 10⁴ cm⁻¹ for 'device quality' amorphous silicon films. Furthermore the calculated values for the three µc-Si:H films all had, at the same wavelength of the spectrum, relatively high values (greater than 1 × 10⁴ cm⁻¹) decreasing with the increase in crystallinity. This improved light absorption of the two-phased material was attributed to the remaining amorphous network in the films, which allowed direct optical transitions.

Electrical properties

Table 2 summarises the electrical characteristics of Samples 2–5. It transpired from the table that the dark conductivity values were low, a sign that the films were truly intrinsic and the incorporation of impurities had been minimised. They compared well with the reported value for an amorphous silicon ‘device quality’ film of <1 × 10⁻¹⁰ Ω cm⁻¹. The values recorded for the activation energy supported this observation, as they agreed with the calculated energy gap values found in the range ~1.6–1.9 eV. The photoresponse of Sample 5 was maintained particularly high for a film above the edge of crystallinity, showing that the carriers recombination on the grain boundaries was insignificant. We conclude that the film contained a sufficient amount of hydrogen, as depicted in the last column of Table 2, such that the grain boundaries were passivated very well. A degradation study was conducted on the sample to investigate its stability under illumination. Figure 7 displays the measured photocurrent values as a function of the light-soaking time. The stability of Sample 5 (Table 1) was high as the change in photocurrent after more than 200 h of illumination was observed to be far less than one order of magnitude. The measured photocurrents and hydrogen content as a function of the deposition pressure. The H₂ dilution ratio was maintained at 87%.

small value of the dark current was not affected by the illumination, and thus maintained the photoreponse at a high level. Compared to the graph of an amorphous Si film identified as Sample 1 in Table 1, it follows that the nanocrystalline material showed an improved stability against light exposure. This result is in agreement with other published reports.32 The noticeable difference between our results and those reported by Soufﬁ et al.23 is the sharper drop of the photoconductivity for our amorphous film in the first 20 h of illumination. On the other hand, the photocurrent of the two ﬁlms probed in our investigation stabilised after 200 h of illumination. The last observation was one of the advantages of a-Si:H ﬁlms deposited by HWCVD over those deposited by plasma-enhanced chemical vapour deposition (PECVD).

Those deposited by PECVD reportedly do not attain a stable photoconductivity after several hours of illumination,24 in contrast to the HWCVD samples investigated in this study.

Conclusion

An increase in the deposition pressure at a ﬁxed optimum hydrogen dilution ratio in the HWCVD process can be used to produce nc-Si:H intrinsic ﬁlms that are both photosensitive and stable against light degradation effects. It has been shown that at a ﬁxed relatively low hydrogen dilution ratio of 87%, the ﬁlms remained amorphous up to 60 µbar. When the hydrogen dilution ratio was increased to 92%, a gradual increase of the process pressure allowed the crystallisation of the ﬁlms at a much lower pressure of 30 µbar. This method of inducing crystallinity using an increase in deposition pressure is particularly beneﬁcial because relatively high deposition rates are achieved, although a saturation point will ultimately be reached due to the limited surface area of the ﬁlm catalyst. In this study, a deposition rate as high as 4.7 Å s⁻¹ was achieved for a ﬁlm at the edge of crystallinity with a crystalline volume fraction of 6%. The electrical properties studies have shown that this layer has a good photoreponse of 6.08 × 10³ while the degradation measurements have shown that the sample is quite stable.
